1 INTRODUCTION

1.1 Background and Purpose

This Shoreline Management Plan (Plan) has been developed with funding from the Keith Campbell Foundation and the Chesapeake Bay Foundation in response to the Anne Arundel County's desire to create a comprehensive shoreline management plan for the South River coast (Figure 1). The study area includes shorelines along the South River from Chesapeake Bay west and north to just above the Route 2 Bridge. The total shoreline assessed for the study is about 82 miles.

This study makes recommendations that address shoreline erosion on an as-needed basis. The impacts of "doing nothing" to the shoreline are assessed as are various structural and non-structural alternatives. Recommendations include shoreline protection strategies that are relatively non-intrusive to natural surroundings yet effective within the context of long-term shoreline erosion control. The strategies may combine stone structures such as sills, revetments, and/or breakwaters along with sand nourishment to create a stable substrate for establishing wetland vegetation.

The South River has two basic shoreline settings: 1) those coasts along the main stem of the South River, and 2) the shorelines that occur up the sub-tributary creeks of the South River. A variety of shore types occur along the South River coast including high banks and low banks, marsh fringes and low sandy terraces. An abundance of shore protection structures, mostly bulkheads, presently exist along the reach. The purpose of this Plan is to provide alternatives to shore hardening that will provide shore protection as well as increased habitat value particularly wetlands.

1.2 Components of the Shoreline Management Plan

The South River Shoreline Management plan includes the following components:

- 1) Shoreline Management Plan Synopsis (this document)
- 2) South River Shoreline Management Map ([Appendix A](#))
- 3) South River: Living Shoreline Treatments Summary ([Appendix B](#))
- 4) South River: Living Shoreline Guidelines ([Appendix C](#))

The South River Plan Synopsis summarizes the physical elements and resultant recommendations of the South River and will reference items 2, 3 and 4 as needed for the reader to get more data or information regarding the plan components. The Shoreline Management Plan Synopsis will include 3 basic components:

- 1) South River Shore Plan Elements
- 2) South River Setting: Physical and Hydrodynamic
- 3) South River Shore Treatment Recommendations

2 SHORELINE MANAGEMENT ELEMENTS

2.1 Objectives

The first step in developing a framework for shoreline management is establishing clear objectives toward which erosion control strategies can be directed. In developing the South River Shoreline Management Plan, the following objectives have been given consideration:

- Prevention of loss of land and protection of upland improvement.
- Protection, maintenance, enhancement and/or creation of wetlands habitat both vegetated and non-vegetated.
- Management of upland runoff and groundwater flow which may exacerbate bank erosion.
- For a proposed shoreline strategy, addressing potential secondary impacts within the reach which may include impacts to downdrift shores through a reduction in the sand supply or the encroachment of structures onto subaqueous land and wetlands.
- Providing access and/or creation of recreational opportunities such as beach areas.

These objectives must be assessed in the context of a shoreline reach. While all objectives should be considered, each one will not carry equal weight. In fact, satisfaction of all objectives for any given reach is not likely as some may be mutually exclusive. It is the intention of this study to develop shoreline management schemes for South River by creating a protective shore system using headland breakwaters and beach fill with vegetative plantings in higher energy areas. Sills and marsh plantings will be used where reduced energy allows for successful placement. Living Shorelines will be the emphasis in all recommendations where possible.

In the Chesapeake Bay watershed and elsewhere, increased attention is being paid to the importance of maintaining, creating, and restoring “living” or natural shorelines. The descriptive term “living shoreline” readily conveys the image of a shoreline characterized by wetlands, sand beaches, submerged aquatic vegetation, mud flats, and/or oyster reefs that provide living spaces for a broad array of aquatic and terrestrial organisms. Living shoreline information is designed to complement a voluntary, Bay-wide estuarine and shoreline restoration framework developed by the Chesapeake Bay Foundation and its partners, which waterfront landowners and others can reference to help restore the Bay’s tributaries. The fundamental objective of the living shoreline approach is to protect eroding shorelines while enhancing water quality and habitat for living resources in the Bay. However, the ultimate goal of shore protection must take priority.

2.2 Protection Strategies

Four general shore protection strategies have been considered in the discussion of each shore reach within the study area. These strategies are discussed below. The basic components of recommended strategies, other than do nothing, will be stone, sand, and plants.

1. Do nothing: This option is appropriate where no erosion is occurring or in areas where no infrastructure exists.
2. Defensive approach (stone revetments)

3. Offensive approach (stone sills with wetlands plantings; stone breakwaters and beach fill with plantings; trim trees, grade to the correct elevation and plant marsh grasses; *i.e.* living shorelines)
4. Headland control (stone breakwaters strategically placed)

No Action

Essentially, this strategy allows the natural processes of shoreline erosion and evolution to continue as they have for the past 1,000 years or so as part of the latest sea-level transgression. However, threatened infrastructure, such as roads and buildings, may force the implementation of shore protection strategies. Moving the buildings and roads will delay the problem, but it also might allow more room to initiate a lesser degree of bank work and a reduction in size and scope of shore structures.

Defensive Approach

The Defensive Approach refers to the use of shore protection structures that commonly are placed along the base of an eroding bank as a "last line of defense" against the erosive forces of wave action, storm surge, and currents. For the purposes of this study, stone revetments are the strategy employed.

Offensive Approach

The Offensive Approach to shoreline protection refers to structures that are built in the region of sand transport to address impinging waves before they reach upland areas. These structures traditionally have been groins, but over the past decade, the use of breakwaters has become an important element for shoreline protection. For this study, stone breakwaters and sills will be the strategies employed. Spurs are installed on breakwaters and sills to move the wave diffraction point further offshore to assist in attaining local equilibrium of the shore planform. The use of offensive structures requires a thorough understanding of littoral processes acting within a given shore reach.

Headland Control

Headland control is an innovative approach to shoreline erosion protection because it addresses long stretches of shoreline and can be phased over time. The basic premise is that by controlling existing points of land (*i.e.* headlands) or strategically creating new points of land, the shape of the adjacent embayments can be predicted. A thorough understanding of the littoral processes operating within the reach is necessary to create a stable planform. Headland control can utilize elements of the three previous strategies. The approach was not offered at this level of assessment for the South River.

2.3 Coastal Structures for the South River (refer to [Appendices B](#) and [C](#))

Shoreline stabilization methods can be broadly sorted into three categories:

- **Non-structural:** This involves nourishing existing beaches with additional sand or establishing marsh grass without installing permanent structures to support plants after they are established. These methods are typically, but not always, used where erosion potential is limited – often referred to as low wave energy environments. Other types of non-structural methods are creation or restoration of a fringe marsh on existing substrate or with coir log edging which gives minor bio-degradable structural support. Planting dune grass stabilizes moving sand and promotes growth of dunes on the backshore of beaches.
- **Hybrid:** This option may be employed where greater vulnerability to erosion is present. The approach is a combination of techniques which incorporate sand, wetland and other components along with permanent stone structures that help keep the restored features in place. Examples of hybrid management strategies include fringe marsh creation with stone containment groins, sill, or marsh toe revetment. Marsh restoration with breakwaters can also be considered a hybrid option.
- **Structural:** This utilizes shoreline armoring such as stone revetments and breakwater systems where considerable vulnerability to wave action exists. Breakwater systems allow the creation of beaches and dunes and usually include beach nourishment and dune plantings in their design.

What criteria do you use to determine appropriate shore management strategies?

Management strategies are primarily based on severity of erosion, fetch, and proximity of infrastructure. Also, the level of protection will address return frequency of storms (*i.e.* 10, 25, 50, and 100 yr). Typically, the strategy will protect the adjacent shore from the 25 yr event. It must be remembered that implementing a shore protection strategy is not a one-time effort. Both living shorelines and hard structures require maintenance. Further, recommended strategies will include not only the shore protection strategy, but also how the upland bank should be treated, *i.e.* whether trees should be thinned or banks should be graded. The recommended strategies will have to interface with both the upland and the adjacent shoreline.

3 PHYSICAL AND HYDRODYNAMIC SETTING

The South River trends approximately northwest by southeast, and the mouth can be defined by a line connecting Sanders Point and Thomas Point (Figure 2). It is about five nautical miles (nm) from that line upriver to the Route 2 Bridge. The river width varies along its length from about 0.25 nm at the Route 2 Bridge and gets progressively wider toward the Bay to almost 2.0 nm at the mouth. The width and fetch exposure are variable along its length. The shoreline configuration is a result of antecedent geology and the Chesapeake Bay's fluvial/estuarine pattern. As sea level rose, it flooded the Bay's dendritic drainage.

In the upper reaches (with little fetch) of the Bay's creeks and small rivers, marsh fringes occupy much of the shoreline which in turn attenuate what little wave action occurs there such that shore erosion is minimal. Proceeding down river, the creeks get wider, fetch increases, and wind-driven waves become more significant. Marsh fringes begin to erode and shore erosion increases. Boat wakes can play an added role to the impinging wave climate especially when boat traffic occurs near the shoreline.

When natural marsh fringes become too narrow, storm waves are not attenuated, and they impact the base of the adjacent upland banks. With time, this causes bank undercutting and eventually bank slope failure. Exposed banks are an indication of active shore erosion, and the traditional response by waterfront lot owners is to install a bulkhead or stone revetment. About 82 miles were assessed as part of this study and approximately 36 miles of shoreline (including marinas) has been hardened along the South River (Table 1).

Marine resources, particularly submerged aquatic vegetation (SAV) and oysters, are the subject of extensive restoration efforts around Chesapeake Bay. Shoreline stabilization efforts should consider these and any potential impacts on them, whether positive or negative. The historic foot print of SAV and the location of designated oyster beds are included in the Appendix A.

3.1 Geology and Historical Shore Change

The geologic underpinnings of the South River are shown in Figure 3. From the most recent to the oldest, three types of deposits or strata occur within the lower South River watershed. These include Holocene Alluvium [Qal], Pleistocene Lowland Deposits [Qz] and Upper Paleocene Aquia Formation [TaTbr]. The Holocene Alluvium occurs as the more recent deposit (past 20,000 years) of sand and marsh on the points and spits like Melvin Point, Persimmon Point, Long Point, and Turkey Point. The Lowland deposits are generally composed of silts and clays exposed mostly along the southern shorelines of the lower South River. The Aquia strata, generally sandy in nature, often with various types of fossil shell including oysters and *Turritella*, the screw shell. These deposits are exposed mostly along the north coast of South River except for the headland feature of Brewer Point on the south shore. The nature of sediment input from bank erosion is dependent on what type of strata is eroding.

Table 1. Length of existing structures on the South River.

Structure Type	No. of Structures	Length (ft)
No Shore Structures	667	244,291
Breakwater	6	1,465
Bulkhead	365	93,408
Dilapidated Bulkhead	5	780
Groin	14	7,361
Jetty	2	232
Marina, <50 slips	24	6,824
Marina, >50 slips	14	10,948
Miscellaneous	17	2,014
Riprap	304	69,232
Total Shore Length (ft)		436,552
Total Shore Length (miles)		82.7
Total Length of Hardened shore (ft)		192,262
Total Length of Hardened shore (miles)		36.4

The historic shore positions along the South River are shown in [Figure 4](#). A certain amount of error exists when determining the position of the shoreline from old charts and aerial imagery, particularly when interpreting change up the very narrow creeks. The net long-term erosion is between 1847 and 1994 shorelines. Between the Route 2 bridge and Mayo Point on the south and Hill Point on the north, some of the obvious areas of loss are on the west facing shorelines north of and adjacent to Ferry Point, Melvin Point, and Persimmon Point. Along the south shore, most erosion is on the north facing points like Cedar, Brewer and Mayo. The reach between Mayo Point and Long Point is also very erosive. Shorelines exposed to the open bay are historically erosive as well.

3.2 Hydrodynamics

The mean tide range in the South River is about 1.0 ft. The river shoreline is a series of headlands and embayments caused by secondary drainages (embayments) and interstream divides (headlands). Therefore, the fetch exposure varies along the north and south coasts.

Three basic elements in determining wave climate are: fetch, water depth, and wind speed. Hardaway and Byrne (1999) showed that shore orientation also is a factor. In fact, shorelines along the south shore of the northwest-southeast trending rivers in Virginia have historic erosion rates of 2 to 3 times more than the shoreline facing southward along the northern shorelines. For the purpose of developing a general wave climate along the river, the shore reaches were designated as per [Figure 2](#).

Using Patuxent River Naval Air Station wind data and Solomon's Island tidal data, Basco and Shin (1993) determined a storm scenario of wind speeds of 35 mph and storm surge of +2.5 ft has a 50% probability of occurring in any given year from any given direction, except the southeast where the winds would be 25 mph. Recent storms including Hurricane Isabel and

Tropical Storm Ernesto had significant easterly wind components. Given these, the 35 mph condition was used to apply to a wave climate modeling effort for the South River.

Wind Wave Hindcast Model

Many models are available for wind-wave hindcast modeling. The U.S. Army Corps of Engineers (USACE) model ACES version 1.07 was selected because it provides a quick and simple estimate of wave growth over open-water and restricted fetches in deep and shallow water. Wind waves grow as a result of momentum flux as energy from the air goes across the water and into the wave field. Numerous parameters are accounted for including wind speed, direction, fetch and water depth. These must be input into the model, while other parameters such as temperature differences between air and water and wind reference level corrections, are taken at default values as specified by ACES.

The South River was divided into reaches (Figure 2) along the north and south shorelines. The more exposed reaches along the main trunk were delineated but not the smaller creeks where average fetch exposure is less than 0.5nm. The longest fetch exposure was calculated for each reach from a line that is shore normal from the middle of the reach. The average water depth in that direction also was computed from the most recent nautical chart. Then the selected storm surge was added bringing the average depth to +3.5 ft MLW which was rounded up. The model was run with the 35 mph input. Results are shown in Table 2 titled the South River general wave analysis for wave height (H) and period (T).

The resultant H and T from Table 2 were plotted against fetch exposure (Figure 5). Reach N-03 was taken out because it created an extreme outlier with a fetch of over 36nm. As expected the greater the fetch exposure the larger the impinging wave heights and periods. Site conditions will dictate the actual design of erosion control structures at a given location.

Boat wakes can be an issue especially where boats pass nearby to land. Displacement hulls also tend to create more destructive wakes than planning hulls (Bottin, McCormick and Chasten, 1993).

Table 2. South River general wave climate analysis for wave height and period.

South River General Wave Analysis						
Location	Wave Height (ft)	Period (sec)	*Fetch (nautical miles)	Direction (degrees)	Depth (ft)	Reach Length (ft)
N - 01	1.46	2.23	1.55	254	16	1,350

S -16	0.79	1.6	0.42	0	23	2,550

*Fetch = Effective fetch @ longest exposure with 90° window

Wind = 35 mph; Surge = +2.5 ft which is approximately +4.0 MLW

4 SOUTH RIVER SHORELINE RECOMMENDATIONS

The shoreline strategies for the South River coast are summarized in [Appendix B](#) and detailed in [Appendix C](#). The determination of each strategy was done on sight during several boat trips along the South River coast. The recommendations are found in [Appendix A](#) as a GIS map of the South River. It was a combination of site conditions and best professional judgment as to which strategy was appropriate for each subject shoreline. The first condition was whether an erosion problem existed either on the base of bank or bank face. Bank face erosion almost always means an unstable or erosive base of bank. Bank face erosion was usually seen on the more open shores of South River while base of bank erosion with a relatively stable bank face was often found up the many low-energy, creek shorelines. Exceptions to these tendencies occurred. The “do nothing” option also was considered usually because the erosion was minimal and/or the land use was obviously not residential.

Addressing base of bank erosion, usually up the small creeks, can be done with the N series (N-2 and N-3) strategies as seen in [Appendix B](#) and [C](#). Some hybrids, H series, were recommended up the creeks where a small sill (H-2 variation) was deemed necessary either because of one long fetch exposure, boat wakes or the bank had more critical erosion. Along the more open coasts of the South River, mostly H series options were recommended, particularly H-2, the sill system. Some S series were recommended when both base of bank and bank face erosion occurred. No N series options were recommended on those shorelines, and S series were only recommended on the open South River coasts.

[Table 3](#) shows the type and length of shoreline treatments recommended for the plan. About 14.5 miles of shore options were recommended. Marsh fringe creation with sills, H-2, dominated the recommended strategies at 29,130 ft which includes both low and medium wave energy sites. This is a proven method of shore protection for those shoreline types and their moderate to low wave energy fetch exposures. The second most frequent recommended strategy was fringe marsh restoration with coir log edging, N3, at 18,260 feet. This provided for adding sand to the substrate, and it was felt the coir logs would help initial marsh establishment up the low energy creeks. The third ranked strategy was breakwater systems, S-2, at 8,520 feet of shoreline. The fourth and fifth ranked were N2 and H-2/S-2 combinations at 6,210 ft and 5,000 ft, respectively.

The average length per site for the three most recommended methods are: H-2= 300 ft/site, N3=275 ft/site and S-2 = 500 ft/site. Breakwater systems are usually more applicable to longer reaches of shoreline. However, the fourth (N2) and fifth (H-2/S-2) ranked strategies were 620 ft and 715 ft per site, respectively. This shows that long stretches of very low energy shoreline were deemed suitable for N2 and that once again breakwater systems and combinations therein are more applicable along longer segments of coast.

The level of protection for any given strategy needs to be understood by the waterfront property owner. A +2.5 ft storm surge (+3.5ft MLW) with a 35 mph wind from any given direction has a 50% probability of occurring during any given year as portrayed in the preceding section. This condition will impact the more open shorelines along the South River much more than the sub-tributary creeks. High water without significant wave action is generally not a

problem. The recommended shoreline strategies exposed to moderate wave energy along the South River should offer protection against this condition at a minimum.

Table 3. Recommended shoreline strategies for the South River.

Series Option	Recommendation Type	Length (ft)	No. of Systems Recommended
	Primary Treatment is either Blank or it says "No Action"	3,156	18
H-1	Marsh fringe with groins	204	1
H-2	Marsh fringe with sills	29,126	97
H-2/S-2	Marsh fringe with sills and breakwater system	4,997	7
H-4	Beach replenishment with breakwaters	358	1
H-5	Marsh toe revetment	2,595	4
N-2	Fringe marsh creation or restoration	6,207	10
N-2/N-3	Fringe marsh creation or restoration / with coir logs edging	824	1
N-3	Fringe marsh creation or restoration with coir logs edging	18,262	66
N-?	Assumed N-1 = Beach Fill	361	1
S-1	Revetments	2,071	8
S-2	Breakwater systems	8,520	17
S-3	Spurs	87	1
	Total Length:	76,770 or 14.5 miles

Figure 2. Location of reaches for the general wave climate analysis.

Alluvium
 Interbedded sand, gravel, and silt-clay.
 Sand, very fine to coarse, interbedded with pebbly sand and fine to very coarse gravel. Clay contains beds and lenses of silt-clay, massive to laminated, bearing in places organic matter such as leaves, twigs, and logs. Rare thin peat beds occur. Color tan, brown, and gray.
 Alluvium includes typically heterogeneous, generally poorly sorted sediments, which range from well-sorted to massive. Locally lithologies are mainly quartzite where derived from the Calvert Formation, but contain variable amounts of glauconite where source materials are Nantuxony or Aquia sediments. Alluvium underlies stream channels, floodplains, and adjacent low areas. The most extensive tracts of alluvium in the two-quadrangle area underlie the beds and floodplains of the Severn, and Middle and South Rivers as well as Bacon Ridge Branch and the South River.
 Alluvium is largely the product of channel and overbank deposition within the last 10,000 years. The unit is as thick as 50 feet in places.

Aquia and Brightseat Formations (underlined)
Aquia Formation
 Glauconitic sand and calcareous sandstone.
 Most of the Aquia consists of well-sorted, medium-grained sand, always glauconitic to some degree, but rarely reaching more than 50 percent of the sandstone. Some beds fine or coarse-grained. Color dark gray-green to olive-green in unweathered sand; "salt and pepper" sand where moderately weathered, and rusty-brown with abundant laminae crinoid where deeply weathered. Bedding massive and block-bedded with abundant burrows. Locally highly fossiliferous in places with large sponges and *Trochilites* dominant.
 The Aquia is at the surface over most of the southern half of the South River Quadrangle. Thin, outcrops are numerous, particularly in blocks during the lower Severn and South Rivers where as much as 60 feet of Aquia is exposed in continuous sections. Much of the unit is deeply weathered (to depths as great as 70 feet) to a kinematic clay sand in which much of the glauconite has been oxidized and silt and carbonate leached from the sediment. Boundaries and blocks of unaltered or less-weathered sandstone are common in the soil zone developed on the Aquia and later the surface in places. Below the South River, partial beds or terraced pools of shaly calcareous sandstone as much as 5 feet thick are commonly encountered.
 The Aquia probably accumulated in very shallow marine straits on the inner shelf and record a regressive cycle during the Paleocene. At its thickest, the Aquia totals nearly 150 feet of beds, but it is generally much thinner over the map area.
Brightseat Formation (not mapped separately from Aquia Formation in this area)
 Glauconitic clayey sand.
 Most of the Brightseat consists of predominantly fine-grained, poorly sorted sand with as much as 25 percent of glauconite, but generally much less. Color dark-gray to dark greenish-gray where unweathered; pale-gray to tan in weathered exposures. In places, the sand Brightseat contains some nodules to coarse sand with granules, small pebbles, phosphate clasts, and fish teeth; molluskian shells are uncommon.
 The Brightseat is lithologically similar to the overlying Aquia, and in some areas the contact is gradual, marked by coarsening sand and increasing glauconite content. In most outcrops and boreholes, the two units are not readily separable; consequently, they are mapped as one unit.
 Brightseat sediments probably accumulated on the inner shelf during early Paleocene time. The known thickness is normally 65 feet, but generally less in many areas.

Lowland Deposits (former Talbot Formation)
 Interbedded sand, pebbly sand, gravel, and silt-clay.
 Sand, generally silty or clayey and poorly-sorted. Contains variable amounts of glauconite in deposits along the southeastern flank of the Broad Neck peninsula and below the Severn River. Gravel and pebbly sand is concentrated in the lower part of the unit. In places, thin peats are interbedded in the section, as are black, highly organic clays rich in plant debris. Color mostly pale-gray, tan, or buff, weying to dark gray.
 This unit underlies low flats bordering the Chesapeake Bay and the lower reaches of the South River. Most of the flats lie at 20 feet or less in elevation but some rise to 60 feet in places along their inner margins. The most extensive Q₁ flats in the two-quadrangle area flank the mouths of the Severn and South Rivers as well as extend along the South River from Boyd Point to Turkey Point.
 Much of the Q₁ unit is a graded sequence with gravel and pebbly sand concentrated in the lower portion and silt-clay units capping the section. The silt-clay unit provides the surficial materials over most of the Q₁ lowlands bordering the Bay. In places, drainage is poor and swampy areas prevail. Outcrops are scarce due to low relief and widespread shoreline protection.
 Radiochron dating of organic materials in the Q₁ unit (former Talbot) elsewhere along the Bay indicates a maximum age of 35,000 years. The paleofloors suggest interglacial conditions, that the Q₁ unit is probably Sangrean or older, perhaps mid-Pleistocene. Q₁ strata are as thick as 60 feet in places.

Note: the informal unit name of Q₁ is used on this map for deposits previously mapped as the Talbot Formation, a name currently in disuse. The relationships between Q₁ and the Kiver Island Formation (McCann, 1938a, 1938b; Owens and Davis, 1979) as well as some Quaternary terrace deposits are not unequivocally defined. Until further study reveals the correlation of these units, the informal name of Q₁ is applied to alluvial deposits. Talbot sediments in this area.
